13. Abstract The non-contact atomic force microscopy (NC-AFM) technique is applied to achieve molecular resolution of the immunostimulatory (1->6)-branched b(1->3)glucan scleroglucan. Sample preparation involves deposition of the polysaccharide molecules from an aqueous solution onto a freshly cleaved and atomically smooth mica surface by spraying and air drying. High resolution NC-AFM images have been obtained in air from which the mean polymer chain length (and molar mass) and the mean chain diameter have been estimated from measurements on a sizable sample of molecules.

polysaccharides^{6,22-26} many do not report individual molecular images. In two cases AFM images presented were of continuous two-dimensional periodic arrays rather than images of individual molecules showing chain ends or defects.^{24,25} While information on crystalline structures and molecular cross sections may be available from such images, molecular attributes such as molecular weight, molecular flexibility, and helical defect structures are not accessible. Recently Kirby et. al.²⁶ have reported molecularly resolved images of xanthan molecules on freshly cleaved mica under liquid.

Here we describe application of the NCAFM technique to achieve molecular resolution images of the immunostimulatory^{27,28} (1→6)-branched β -(1→3)-glucan scleroglucan (also known as schizophyllan).^{29,30} Sample preparation involves deposition of the polysaccharide molecules from an aqueous solution onto a freshly cleaved and atomically smooth mica surface by spraying and air drying. Because the forces between the NCAFM probe tip and the biopolymer sample are comparable to those between the polymer chain and the mica surface, no special immobilization of the polymer is necessary, and stable, molecular-resolution NCAFM images of physisorbed polymer molecules are obtained. High resolution (i.e., ≈ 1 Å vertical, 50 Å lateral) NCAFM images have been obtained in air from which the mean polymer chain length (and molar mass) and the mean chain diameter have been estimated from measurements on a sizable sample of molecules. These results can be compared with similar measurements on schizophyllan using transmission electron microscopy (TEM).³¹⁻³³

The conformation and morphology of (1→6)-branched (1→3)- β -D-glucans of fungal origin are of interest, both for the anti-cancer^{27,28} activity and the stiffness of the triple-stranded native helical structure.^{29,30,34,35} It has recently been discovered that these very stiff triple-stranded helical molecules can be dissociated into three random coil chains and subsequently renatured as triple strands in linear and circular forms.³⁶⁻³⁸ At true thermodynamic equilibrium clusters containing just three chains are expected to dominate both the linear and circular helical components in the renatured samples.³⁸ The existence of the circular structures was quite unexpected given the stiff nature of the linear triple helix.³⁷ The circles are reminiscent of circular DNA³⁹, and they also display twisted or supercoiled forms⁴⁰ arising from torsional stress in the helical backbone, although the scleroglucan circles are not

covalently closed.³⁶ We show here that the linear-triple-helix \leftrightarrow circular-triple-helix transformation previously observed in TEM³⁶⁻³⁸ can also be studied using NCAFM.

Experimental Section. Scleroglucan (Actigum CS 6, Ceca S.A., France) was dissolved at 5 g/L in aqueous 0.02% NaN₃, sonicated (20 kHz, 375 W, 1/2 inch tip) at 0° C for 3 h, and centrifuged and filtered to remove particulates. The resulting solution was then fractionally precipitated⁴¹ with isopropanol or acetone to produce ten fractions. Each of the fractions was redissolved in water, dialyzed exhaustively against distilled water, and recovered by freeze drying. Fractions chosen for study were redissolved in water at 1 mg/mL.

Some of the redissolved samples were subjected to a denaturation-renaturation procedure: Aliquots in sealed 10 mL micro-reaction vials were first heated to 160°C for 10 min to disrupt the native triple helix.⁴² These vials were then annealed at 70°C for 23 h and then quenched to room temperature in an ice bath. The annealing temperature was chosen to be within the region of stability of the native triple helix but high enough to reduce kinetic hindrances to reassembly and reorganization of the triple helix.⁴² The scleroglucan fractions, including samples subjected to the denaturation-renaturation procedures and those not so treated, were then diluted by a factor of 30, and 50 μ L of the resulting solutions was pipetted into an atomizer which delivers a fine aerosol onto a freshly cleaved mica surface.⁴³ After drying in air for a few hours, the samples were imaged by NCAFM.

Scanning probe microscope images were obtained using an AutoProbe CP Probe Microscope (Park Scientific Instruments, Sunnyvale, California) equipped with a non-contact AFM probe head. The tips used were V-shaped silicon 2 μ m cantilevers (Ultralevers Model No. APUL-20-AU-25) with a force constant of 13 N/m and resonant frequency of approximately 300 kHz. Imaging was carried out in air at a constant vibration amplitude. Images were stored as 512 x 512 point arrays.

Results and Discussion. A representative NCAFM image of sonicated and fractionated scleroglucan (fraction P-3) in its native triple helical form is shown in Fig. 1a. Individual scleroglucan molecules are clearly resolved in this image. From *ca.* 40 NCAFM images of some 250 individual scleroglucan chains, acquired over the course of several weeks and using different Ultralevers, the number average chain length has been determined to be 189 nm \pm 97 nm. Invoking the known

linear atomic mass density of the scleroglucan helix (2140 nm^{-1}),²⁹ we find $M_n = 4.15 \pm 1.71 \times 10^5 \text{ g/mol}$. The distribution of lengths yields for $M_w/M_n = 1.26$ and provides a measure of the effectiveness of the fractional precipitation procedure.

From the same data set the average chain width (measured in the direction normal to the long axis of the chain and parallel to the mica surface) and chain height (measured in the direction normal to the surface) are $18 \pm 7 \text{ nm}$ and $0.80 \pm 0.5 \text{ nm}$, respectively. A sample height profile corresponding to the trace indicated in Fig. 1a is shown in Fig. 1b. We take the measured mean height to be an faithful reflection of the thickness of the native triple stranded helix. Crystallographic studies of scleroglucan fibers⁴⁴ suggest, however, a triple helix diameter of *ca.* 17 \AA . Failure of the present height measurements to reproduce this dimension exactly may be related to the presence of one or more layers of water on the mica surface adjacent to the adsorbed macromolecule.⁴⁵ Other investigators have reported similar discrepancies between macromolecular thicknesses measured by scanning probe microscopy and the dimensions expected from independent information.⁴⁶ Other possible explanations for the observed discrepancy are that the polysaccharide molecules are slightly deformed because of spreading and flattening that may occur upon drying of the sample and adhesion to the mica surface.

The measured mean width provides, in effect, a measure of the thickness of the probe tip averaged over the several tips used to accumulate the data convoluted with the *ca.* 17 \AA thickness of the scleroglucan triple helix. The alignment of the molecules evident in the image may be due to ordering of the polymer chains along the crystal planes of the mica surface or perhaps to orientation effects associated with evaporation of the solvent.³¹ These orientation effects serve to exaggerate the stiffness of the scleroglucan triple helix.

Fig. 2a shows an NCAFM image of the same scleroglucan fraction after having been subjected to the denaturation-renaturation process. A mixture of linear, cyclic, and hairpin structures with some clusters of higher molecular weight is observed. The mean diameter of some 155 circles appearing in 12 separate NCAFM images is $33 \pm 12 \text{ nm}$, corresponding to a mean circumference of 104 nm and $M_n = 2.22 \pm 0.26 \times 10^5 \text{ g/mol}$ for the circles, assuming the same linear mass density as for the linear scleroglucan triple helix. For the sampled group of circles $M_w/M_n = 1.13$. We do not know at this point why M_n for the circles in the

renatured sample is smaller than that for the undenatured starting material. It may simply reflect sampling error, or it may result from degradation of the single strands during the heating procedure or reflect the probability distribution for circle formation as a function of single strand chain length.³⁷

Fig. 2b shows a cross-section of the height profile corresponding to the indicated circle shown in Fig. 2a. The measured height and width dimensions of the linear and circular components of the renatured sample (Figure 2a) are approximately the same, and they agree closely with those of the undenatured triple helix of scleroglucan reported in Figure 1. The average length of the linear structures in renatured samples is 85.7 nm, less than half the mean length before denaturation. This, coupled with the mean circumference of the circles in the renatured samples strongly suggest that some chain degradation accompanies the thermal denaturation of the native linear triple helices.

Summary. Atomic force microscopy operating in the attractive, or non-contact mode, is used to image individual triple-helical scleroglucan molecules on a mica surface in air. The long range attractive forces involved in NCAFM imaging are much weaker than the repulsive forces measured in conventional AFM with the result that adsorbed molecules are not swept away, damaged, or deformed. Because the interaction forces between the NCAFM tip and the biopolymer sample are approximately equal to the van der Waals attractive forces between the polymer chain and the mica surface, no special immobilization of the polymer to the substrate is required, and stable, molecular-resolution imaging of physisorbed polymer molecules is possible. Using this technique we have been able to monitor the linear-triple-helix to circular-triple-helix transition in scleroglucan routinely and reproducibly.

Acknowledgments. This work has been supported by NIH Research Grant GM 33062 to DAB, by NIH Traineeship GM 07311 to TMM, and by the ONR Grant 400X119YIP to RMP. We would like to thank Park Scientific Instruments for donation of some of the cantilevers used in this study. TMM would like to gratefully acknowledge Dr. Mike D. Kirk at Park Scientific Instruments for valuable discussions concerning this work.

Figure Legends

Figure 1. (a) NCAFM image of native aqueous scleroglucan fraction P-3 deposited on mica substrate. Sample prepared as described in the text. Horizontal scale shown along bottom and right axis. (b) Trace taken along solid black line running approximately left \rightarrow right in (a) and intersecting one scleroglucan chain: apparent chain thickness in the dimension normal to the substrate is shown on the vertical axis, approximately 9 Å, and between wedged-shaped markers in the horizontal direction, 127 Å.

Figure 2. (a) NCAFM image of aqueous scleroglucan fraction P-3 deposited on mica substrate following denaturation-renaturation. Sample prepared as described in text. Horizontal scales shown as in Fig. 1a. (b) Trace taken along solid black line running left \rightarrow right in (a) across one isolated scleroglucan circle; apparent chain thickness in the dimension normal to the substrate is shown on the vertical axis. The selected circle has a diameter of 30.8 nm, as measured between the peak maxima.
